

**METHOD, APPARATUS, EDGE ROUTER AND SYSTEM FOR PROVIDING QOS GUARANTEE**

**Field of the Invention**

[0001] The present invention relates to the field of network  
5 communication, and particularly to a method and an apparatus for  
providing QoS (Quality of Service) guarantee, as well as an edge  
router and a system for providing QoS guarantee based on the edge  
router.

10

**Background of the Invention**

[0002] With the continuously expanding of the scale of computer  
networks and the rapidly developing of large internets, routing  
technology has become gradually a critical technology among the  
network technologies, and routers have become the most important  
15 equipments in a network. A router operates at the third layer of the  
OSI (Open System Interconnect) Model, which is named the network  
layer. A router differentiates different networks to implement  
interconnection and isolation between networks and keep the  
independence of the individual networks by utilizing the 'logic'  
20 network address (i.e., IP address) defined in the network layer.

[0003] During the transition of the current telecommunication  
network from circuit-based technology to packet-based technology and  
the evolution of multiple independent dedicated service networks  
toward an integrated multi-service network, IP (Internet Protocol)  
25 technology has been widely accepted as the public user network  
interface of the Next Generation Network service. With the  
introducing of the MPLS (Multi-protocol Label Switching), an IP  
network is not only able to keep sufficient flexibility but also able  
to provide manageable and operable services that may be better than  
30 best-effort delivery service, while possessing certain connection

oriented characteristic. It is an important feature of the Next Generation Network to provide abundant public operating services by the coexistence and cooperation of the intelligence inside a network and the intelligence at the edge of the network. Accordingly, a multi-service edge router at the edge of a network is very important and necessary for constructing an integrated multi-service network.

[0004] TCP/IP (Transmission Control Protocol/Internet Protocol) technology, as originally conceived, offers only a best-effort delivery service without QoS (Quality of Service) guarantee. However, it is difficult for the best-effort delivery service to meet the requirements of multimedia service for delay, jittering and packet loss rate in a multi-service environment, since different services and users have different requirements for quality and security of network service. In view of this, the QoS technologies and mechanisms, such as InterServ (Integrated Service), DiffServ (Differentiated Service) and policy control, have been presented. Nevertheless, the problem of QoS in a packet-based network has not been resolved up to now. The relative QoS mechanism provided by DiffServ can not find a solution to the traffic congestion or optimize the performance of a network, and the quality of network service provided by DiffServ is uncontrollable, immeasurable and not absolutely guaranteed. The absolute QoS mechanism provided by InterServ requires large network overhead, and has a serious problem on extensibility regarding the number of application flows supported and network scale. MPLS traffic engineering technology still can not provide a real-time control system for scheduling of application flow level. Considering the construction of the next generation network by employing IP techniques, the QoS problem has become a critical bottleneck to be broken during network convergence and evolution.

[0005] Today's IP networks are all of layered architecture, i.e. all

contain a packet-based core network and various types of access networks in order to achieve good manageability, stability and extensibility. The core network routes and switches packets in high speed, having high reliability and redundancy. The access networks support various user access modes, such as Ethernet LAN, xDSL (Digital Subscriber Line), HFC (Hybrid Fiber Coaxial Cable), etc., and provide network service control functions such as access control, authentication billing, network security, VPN (Virtual Private Network) and QoS classification, and the like.

10 [0006] An edge router locates at the egress of an access network and the ingress of a core network, the multi-service supporting capability of which is the most important with respect to whether the network can support various services, and the QoS-supporting capability of which plays an important role in QoS framework of an IP network. A multi-service edge router has to possess capabilities of flow classification, traffic control (including metering, marking, dropping/shaping and queuing) and traffic aggregation.

15 [0007] In the IntServ model, a service traffic flow sender installs and refreshes in advance the information of the resource reservation state at the respective forwarding nodes on the service traffic flow path(s) via Resource Reservation Protocol, thus establishing a virtual connection with QoS guarantee. The respective forwarding nodes recognized and schedules each of the service traffic flows according to the resource reservation soft state (means that a periodic maintaining of the resource reservation refresh packets is needed). To maintain the virtual connection, the service traffic flow sender periodically refreshes the resource reservation soft state to the network via Resource Reservation Protocol until the application layer shows a request to end the reservation or the network feedback can not provide reservation for the application.

20  
25  
30

Resource Reservation Protocol is a path-coupled signaling protocol, and the path of the protocol packet is completely the same as the service traffic flow path.

[0008] The functional block diagram of the respective forwarding nodes (including the edge router) in the IntServ model is shown in Fig.1, the functions include RSVP (Resource Reservation Protocol) protocol processing, RSVP soft state maintaining, routing, policy control, admission control, packet classification, packet forwarding and packet scheduling. To support the IntServ model, the edge router has to possess these functions as well, all of which are directed to application flows including admission control, policy control, RSVP state maintaining, packet classification, queue scheduling. There will be thousands of or even more states, classifications and queues to be maintained if the granularity of control is refined to application flow level.

[0009] Although the Intserv model can be used to achieve a refined granularity of resource control in application flow level, it is necessary for the routing equipments (including the edge router) to record a large amount of RSVP soft state information of application flows and to handle a great deal of periodic RSVP soft state refresh packets. Each of the application flows occupies a scheduling queue, thus resulting in a high requirement for the performance of the routing equipments, and a serious issue of extensibility in application to medium/large networks. For this reason, such QoS technology is not used widely in the IP network operated by the telecommunication operator.

[0010] Even if IntServ is only applied in access networks and DiffServ or MPLS TE (Multi-protocol Label Switching Edge Router) is used in a core network, the burden of the edge router is not relieved at all. The edge router still has to record a large amount of RSVP soft state

information and to handle a great deal of periodic RSVP soft state refresh packets, and to provide the aggregating and mapping functions of QoS classification.

[0011] The process of the classification and the conditioning of traffic by an edge router in DiffServ model is shown in Fig.2: the ingress node at edge of a network performs classification and conditioning, including metering, marking, dropping and shaping, to the packet traffic according to the static SLA (Service Level Agreement). Wherein the marking refers to the process of setting a value for the DSCP(Differentiated Service Code Point) domain in each packet. Each DSCP code represents a class of aggregated traffic (at most 64 classes), and it is required that the same specific QoS forwarding process is performed at all the network nodes. Each hop node inside the network forwards a packet depending on the value of the DSCP domain according to the configured QoS mechanism, such PHB (Per-Hop Behavior) includes resource allocation, queue scheduling, dropping policy, etc..

[0012] The DiffServ model employs the concepts of coarse classification and aggregation in which different classes receiving different services in the network, without negotiating in advance on resource reservation. The control is coarser grained, there are generally 6 QoS classes (64 classes at most), each of the classes having several queues. By conditioning the behavior of the boundary node(s), the incoming traffic to each QoS class of the network may be controlled. The states of the flows are not recorded inside the network, but are processed for each packet according to the marked QoS type, thereby the signaling protocol processing is omitted.

[0013] Fig. 3 is a functional block diagram of an edge router in the DiffServ model.

[0014] The input interface and the output interface both perform

classification, metering, processing and queue scheduling, all of which are performed with respect to the level of traffic aggregation, without signaling negotiation and state maintaining of application flow, thereby the number of the queues required are reduced greatly.

5 The specs of flow classification and PHB behavior for each class of service can be configured locally by command lines, or be configured by network management server through provision of SNMP (Simple Network Management Protocol) Interface, or be configured by policy server through provision of COPS (Common Open Policy Service) Interface.

10 [0015] Such DiffServ model of providing classified services is more suitable for a large-scale core network. However, its flow classification spec is rather coarse grained, and is generally based on physical port or logic port instead of application flow. Due to the temporality and frequent variations of the application flow, the identity (the initiation and destination IP addresses, port numbers and protocol types) of the application flow and the desired QoS type are not known by the network management and the policy management, thus an edge router is unable to have the ability of classification and identification in application flow level by configuring the management interfaces. Moreover, because the service of the same class will share the resource of this class, and there will exist a certain degree of resource competition between those services with the same priority, the end-to-end QoS may not be guaranteed.

25 [0016] The operators generally try to avoid the problem of resource competition between services with the same priority according to the statistic characteristic by means of a large bandwidth and a light load, that is to say, the average utilization of the control resources of a core network is no more than 50% or 70%, and the average utilization of resource for the services with higher priorities is

no more than 20%. However, the cost of a network with a large bandwidth and a light load is much high, the wider the bandwidth is, the bigger the absolute value of the waste is. Once the load is over 50%, serious traffic congestion problem will occur; furthermore, what the  
5 DiffServ provides is only a relative QoS, namely a better QoS than that of the best-effort delivery, which can not provide end-to-end absolute QoS guarantee for the application flow.

### Summary

10 [0017] In the first aspect of the present invention, there is provided a method for providing guarantee of quality of service (QoS) guarantee, so as to solve the problems in the prior art that an edge router is overloaded and does not possess the ability of classification and identification in application flow level, and to  
15 cause the edge router to provide for application flows precise QoS guarantee and QoS routing control.

[0018] In the second aspect of the present invention, there is provided a device for providing QoS guarantee.

[0019] In the third aspect of the present invention, there is provided  
20 an edge router for providing QoS guarantee.

[0020] In the fourth aspect of the present invention, there is provided a system for providing QoS guarantee based on an edge router, so as to overcome the limitation in the prior art that neither the integrated service model nor the differentiated service model can  
25 guarantee the QoS in application flow level, and to meet the requirements that a variety of telecommunication services are borne by a packet-based network.

[0021] In view of this, the present invention provides technical solutions as follows:

30 [0022] A method for providing quality of service(QoS) guarantee,

wherein the method includes the steps of:

- A. creating a service traffic flow classification table;
- B. establishing a plurality of label switching paths;
- C. configuring the attributes of the label switching paths;
- 5 D. classifying and conditioning the service traffic flows entering a core network at a downlink interface of an edge router according to the service traffic flow classification table;
- E. forwarding the processed service traffic flows by an uplink interface of the edge router according to the attributes of the label
- 10 switching paths.

[0023] The step A includes the steps of:

- A1. obtaining service traffic flow information, the service traffic flow information includes flow classification spec, priority, QoS class, bandwidth requirement, path information, in which the flow
- 15 classification spec includes port-level flow classification spec and/or user-level flow classification spec and/or application-flow-level classification spec;

- A2. creating the service traffic flow classification table according to the obtained service traffic flow information.

- 20 [0024] Particularly, the step A1 is: configuring the service traffic flow information statically.

- [0025] Particularly, the step A1 is: directly obtaining the service traffic flow information from a service control equipment.

- 25 [0026] Particularly, the step A1 is: indirectly obtaining the service traffic flow information from the service control equipment through a resource control equipment.

- [0027] Particularly, the step B is: configuring the label switching paths statically at the uplink interface of the edge router.

- 30 [0028] Particularly, the step B is: establishing the label switching paths dynamically via constraint-routing label distribution protocol (CR-LDP) or resource reservation protocol-traffic engineering (RSVP-TE).

- [0029] The step B further includes the step of:

constructing an edge-to-edge label switching path concatenated pipe or a virtual multi-protocol label switching network on the core network by using the label switching paths.

[0030] Particularly, the step C is:

- 5        configuring traffic class, priority, QoS class, bandwidth attribute of the label switching paths by traffic planning and traffic engineering statistics.

[0031] The service traffic flow classification table comprises:

- 10        service traffic flow identification, priority, QoS class, bandwidth requirement, and path information.

[0032] The step D comprises the steps of:

- D1. obtaining the service traffic flow identification;  
      D2. looking up the service traffic flow classification table according to the service traffic flow identification;  
15        D3. classifying and conditioning the service traffic flow entering into the core network according to the corresponding service traffic flow information in the service traffic flow classification table.

[0033] The step D3 includes the steps of:

- 20        D31. classifying and marking the service traffic flow according to the corresponding priority and QoS class;  
      D32. shaping and policing the service traffic flow according to the corresponding bandwidth requirement;  
      D33. selecting the forwarding mode of the service traffic flow  
25        according to the corresponding path information.

[0034] The forwarding mode of the service traffic flow includes:

- best-effort delivery in accordance with network protocols;  
      delivery through the corresponding label switching paths of this class of traffic.

30        [0035] The step E includes:

- E1. steering the service traffic flow to the egress router of the core network via network protocols when the best-effort delivery in

accordance with network protocols is selected as the forwarding mode of the service traffic flow;

5 E2.steering the service traffic flow to the egress router of the core network through the label switching path concatenated pipe or the virtual multi-protocol label switching network when the delivery through the corresponding label switching path of this class of traffic is selected as the forwarding mode of the service traffic flow.

[0036] The method further includes the step of:

10 F. modifying the service traffic flow classification table when the service traffic flow is changed.

[0037] The step F includes:

obtaining and adding the service traffic flows information of a session into the service traffic flow classification table when  
15 the session is established;

canceling the service traffic flow information of the session from the service traffic flow classification table when the session is ended.

[0038] The present invention further provides an apparatus for  
20 providing QoS guarantee, wherein the apparatus includes:

a service traffic flow information obtaining means, for creating a service traffic flow classification table;

a label switching path establishing means, for establishing a plurality of label switching paths;

25 a label switching path configuring means, for configuring the attributes of the label switching paths;

a first performing means, for classifying and conditioning service traffic flows entering into a core network according to the service traffic flow classification table; and

30 a second performing means, for forwarding the processed service traffic flows according to the attributes of the label switching paths.

[0039] The present invention further provides an edge router based

on the above mentioned means for providing QoS guarantee, which includes a configuration management interface, wherein the edge router further includes:

5 a service traffic flow information obtaining means, for creating a service traffic flow classification table;

a label switching path establishing means, for establishing a plurality of label switching paths;

a label switching path configuring means, for configuring the attributes of the label switching paths;

10 a first performing means, for classifying and conditioning the service traffic flows entering the core network according to the service traffic flow classification table; and,

15 a second performing means, for forwarding the processed service traffic flow according to the attributes of the label switching paths.

[0040] The present invention further provides a system based on the above mentioned edge router for providing QoS guarantee, which includes a service control equipment, a resource control equipment, and an edge router, wherein the edge router includes:

20 a service traffic flow information obtaining means, for creating a service traffic flow classification table;

a label switching path establishing means, for establishing a plurality of label switching paths;

25 a label switching path configuring means, for configuring the attributes of the label switching paths;

a first performing means, for classifying and conditioning the service traffic flows entering into the core network according to the service traffic flow classification table; and

30 a second performing means, for forwarding the processed service traffic flows according to the attributes of the label switching paths.

[0041] It can be seen from the above technical solutions provided by the present invention that a edge-to-edge LSP concatenated pipe

or a virtual MPLS network may be formed on the core network by establishing a plurality of LSP (Label Switching Path) at the uplink interface of the edge router in the present invention. This makes it possible to select to steer service traffic flows to the Internet egress router by way of IP or steer service traffic flows to the Internet egress router through LSP concatenated pipe or virtual MPLS network according to the traffic class. Thus, precise QoS guarantee and QoS routing control can be provided for application flows between the edges of the core network, thereby meeting the requirements for a packet based network to support various telecommunication services simultaneously. Moreover, since the QoS control in application flow level is performed only at the edges, while the traffic control in LSP level is performed at the core of the network, high-speed forwarding capability and simplicity in the core of the network are ensured.

### Detailed Description of the Embodiments

[0049] The present invention aims to form an edge-to-edge LSP concatenated pipe or a virtual MPLS (Multi-Protocol Label Switching) network on a core network by establishing a plurality of LSPs (Label  
5 Switching Path) at the uplink interface of an edge router. Thus, when a service session is established, the service traffic flow information of the service session is obtained and recorded by the edge router. When packets are processed by a downlink input interface, the downlink input interface selects the mode for sending the service  
10 traffic flow according to the recorded service traffic flow information, labels the service traffic flow with MPLS multi-layer label stack, and sends it to the LSP concatenated pipe or the virtual MPLS network for this class of service traffic at the uplink output interface. The uplink output interface performs classification and  
15 conditioning for the LSP traffic according to the LSP attributes when sending the packets, thus providing QoS guarantee in application flow level for the service traffic flow.

[0050] It is known to the skilled in the art that a router connects the nodes of a network, and the packet forwarding process of the router  
20 according to the TCP/IP protocols is as follows:

[0051] (1) an interface receives a packet. In this step the processing for the network physical layer is performed, that is, the coded and modulated data signal is restored into data. Different physical network mediums determine different network interfaces. For a router,  
25 for example, there is a 10 Base-T (10 Mbps base-band transmission over twisted pairs) Ethernet interface corresponding with the 10 Base-T Ethernet, an SDH (Synchronous Digital Hierarchy) interface corresponding with the SDH, and a V.35 interface corresponding with the DDN (Digital Data Network).

30 [0052] (2) Depending on the network physical interfaces, the router

invokes the corresponding functional module in the link layer (the second layer of the seven-layer network protocol) to interpret and process the link layer protocol header in this packet. The process in this step is relatively simple, and is mainly for data integrity verification, such as CRC (Cyclic Redundancy Coding) check, frame-length check.

[0053] (3) After the integrity verification for a data frame is completed in the link layer, the router begins to deal with the IP layer of this data frame. This process is the kernel of the functions of a router. According to the destination IP address in the IP header of the data frame, the router queries the routing table for the IP address of the next hop, the TTL (Time to Live) field in the header of the IP packet begins to decrement, and a new checksum is calculated. If the type of the network interface for receiving data frames is different from that of the network interface for forwarding data frames, the IP packet may be sectioned or regrouped because of the specification on the maximum frame length.

[0054] (4) According to the IP address of the next hop found from the routing table, the IP packet is sent to the corresponding outgoing link layer, encapsulated with a corresponding link layer header, and sent out through an output network physical interface.

[0055] The edge router locates at the boundary between the access network and the core network, a networking structure of which being shown in Fig.4. Different users log respectively onto different wideband remote access servers through the local network then connect to the core network via the edge router, and connect user traffic to the Internet egress router via the core network. The edge router often aggregates a large amount of communication traffic and transmits packets between networks. An edge router has to have a plurality of interfaces having different speeds and adapted for

different types of communication traffic to support, for example, Ethernet, ATM (Asynchronous Transfer Mode) and SONET (Synchronous Optical Network). The edge router provides growing technical supports for many services, such as multi-protocol label switching, QoS (Quality of Service) performing, voice transferring over packet, IP multicasting and wireless network. It is necessary for the edge router to meet various requirements of users, ranging from simple networking to complex multimedia services and VPN services etc., which requires the edge router to have strong realization capability on both hardware and software. The present invention is to enable the edge router to provide QoS guarantee in application flow level in multi-service packet-based network on the basis that the edge router supports DiffServ (Differentiated Service) and MPLS techniques.

[0056] The present invention will be described in further details in conjunction with the appended drawings and the embodiments.

[0057] Referring to Fig.5, in which a flow chart of the method according to an embodiment of the present invention is shown, which includes the following steps:

[0058] Step 501: obtaining service traffic flow information at the downlink interface of the edge router (i.e. the interface connecting with an access network node). The service traffic flow information includes flow classification spec, priority, QoS class, bandwidth requirement, and path information etc.. The flow classification spec includes port-level traffic classification spec and/or user-level traffic classification spec and/or application flow-level traffic classification spec.

[0059] The service traffic flow information can be configured during the initialization of a service session, or can be obtained from service control equipment.

[0060] The service control equipment is able to have the knowledge of the starting and terminating time of the traffic exactly, as well as parameters such as the identity, the application type and the QoS requirement of the traffic, so the edge router may have the ability of classification and identification in application flow level by providing a QoS control interface to receive the information. The QoS requirement of the service traffic flow can be exchanged directly between the service control equipment and the edge router through this QoS control interface. Also, the QoS requirement of the service traffic flow can be forwarded by the service control equipment through a resource control equipment. The resource control equipment performs exchanging with the edge router directly through this QoS control interface. Thus, as a service session is initialized, the edge router receives the identification (a quintuple or a triplet), the priority, the QoS class, the path (MPLS multi-layer label stack) and the bandwidth requirement of service traffic flows of the session from the service control equipment or the resource control equipment through the QoS control interface.

[0061] Step 502: establishing a service traffic flow classification table according to the obtained service traffic flow information. The edge router creates an entry in the service traffic flow classification table to recode the received service traffic flow information.

[0062] The service traffic flow classification table includes the following information: service traffic flow identification, priority, QoS class, bandwidth requirement, path information.

[0063] Step 503: establishing a plurality of LSPs. The LSPs can be established at the uplink interface of the edge router by means of static configuration, or can be established dynamically through CD-LDP (Constraint-Routing Label Distribution Protocol) or RSVP-TE

(Resource Reservation Protocol - Traffic Engineering) signaling.

[0064] CR-LDP is an LDP (Label Distribution Protocol) signaling based on MPLS (Multi-Protocol Label Switching) standard, which can be used in establishing and maintaining the LSPs capable of guaranteeing the  
5 IP CoS (IP Class of Service) services. CR-LDP utilizes UDP (User Datagram Protocol) to find MPLS peer-to-peer network entity, and uses TCP (Transmission Control Protocol) session to distribute label request. CR-LDP does not demand the LSR (Label Switching Router) to update the state of each LSP, because it utilizes TCP to transmit  
10 control message, and to provide reliable message transfer, without additional bandwidth consumption. To maintain the connection between the neighboring nodes, CR-LDP has the function of checking the existence of the neighboring nodes and monitoring the TCP connection. CR-LDP contains five types of messages, which are Discovery, Session,  
15 Advertise, Notification, and Control respectively, each of the messages employing TLV (Type-Length-Value) to encode the common structure.

[0065] RSVP is a signaling protocol, which is used by the host to establish and control the resource reservation tunnels for its  
20 service traffic flows in the IP network. MPLS traffic engineering also needs to reserve resource in the IP network, this is similar with the resource reservation of the RSVP, so that RSVP can be extended as RSVP-TE, and used in traffic engineering. RSVP-TE has many additional objects supporting the establishment and management of  
25 the explicitly routed LSP on the basis of the conventional RSVP protocol, and is responsible for distributing the label information of the MPLS LSP. RSVP-TE occurs between the ingress and the egress routers of the traffic trunk, employs traffic parameters of IntServ (Integrated Service) to describe the QoS parameters thereof, and  
30 utilizes PATH message and RSEV message to establish an LSP tunnel.

[0066] Step 504: constructing an edge-to-edge label switching path concatenated pipe or a virtual multi-protocol label switching network on the core network by the established LSP.

[0067] Step 505: Configuring the attribute(s) of the LSP.

5 [0068] The attributes of LSP, such as traffic classes, priority, QoS class, bandwidth etc., are configured by traffic planning (for example, the traffic peak value of a certain traffic such as voice traffic every day, the required QoS class and bandwidth of these traffic etc.) and traffic engineering statistics (for example, the  
10 distribution of the traffic load over the network, the distribution of congestion and bottle-neck nodes, the proportion of the bandwidth that could be occupied by the traffics of various QoS classes to guarantee the network performance), so as to bear different classes of service traffic. The traffic classes can be classified according  
15 to the QoS class or the application types such as VoIP (Voice over IP)/VoD (Video on Demand)/WEB (World Wide Web) etc., and is substantially a number of traffic aggregation classes.

[0069] Step 506: obtaining the service traffic flow identification of a service session;

20 [0070] Step 507: looking up the service traffic flow classification table according to the service traffic flow identification.

[0071] Step 508: performing classification, conditioning and MPLS label stack encapsulation to the service traffic flows entering into the core network according to the corresponding service traffic flow  
25 information in the service traffic flow classification table.

[0072] The label switching path mentioned in the above steps may be MPLS LSP technique, and can also be substituted by any other techniques that have traffic aggregation function, such as L1VPN (Layer 1 VPN, VPN: Virtual Private Network), L2VPN (Layer 2 VPN),

L3VPN (Layer 3 VPN), Tunnel, VLAN (Virtual Local Area Network) etc., namely, it is not limited to MPLS LSP techniques.

[0073] The flow classification specs can be in port level, which will be recognized by physical port number or logic port number; or can  
5 be in user level, which will be recognized by IP address, MAC (Medium Access Control layer) address and VLAN ID (Virtual Local Area Network Identity); or further, can be in application flow level, which will be recognized by IP quintuple (source IP address, destination IP address, source port, destination port and protocol type) or triplet  
10 (destination IP address, destination port and protocol type).

[0074] The classified traffic is conditioned according to the DiffServ standard (IETF-rfc2475) of IETF. The conditioning includes the following steps of:

[0075] Classifying and marking the service traffic flow according  
15 to the corresponding priority and the requirement on QoS class;

[0076] Shaping and policing the service traffic flow according to the requirement on the bandwidth;

[0077] Selecting the forwarding mode of the service traffic flow according to the corresponding path information: forwarding in the  
20 best-effort delivery mode of IP or stamping with a MPLS multi-layer label stack, sending into the LSP pipe or the virtual MPLS network of this class of traffic at the uplink output interface.

[0078] Then, it proceeds to step 509: forwarding the processed service traffic flow by the uplink output interface of the edge router  
25 according to the attribute(s) of the LSP.

[0079] The service traffic flow will be connected to the egress router in the Internet via IP protocols if the selected forwarding mode is the best-effort delivery according to IP protocols;

[0080] The service traffic flow will be connected to the egress router

in the Internet through LSP pipe or virtual MPLS network if the selected forwarding mode is corresponding LSP delivery of this class of traffic.

[0081] The uplink output interface of the edge router performs  
5 classifying and shaping of the LSP traffic according to the LSP attribute(s) when it sends packets, wherein the classifying and shaping include measuring, marking, dropping and policing of the MPLS packets.

[0082] The network core node pops out and forwards the labels  
10 according to the MPLS multi-layer label stack and the priority of the MPLS packets that the edge router marked in the packet header, and measures, drops, shapes and monitors the LSP traffic according to the LSP attribute(s).

[0083] It is necessary to condition the service traffic flow  
15 classification table according to the change of the service traffic flow when the service traffic flow of a service session changes. At the QoS control interface, the service control equipment or resource control equipment will notify the edge router to cancel the service traffic flow information prior to the change and set the service traffic flow information following the change. That is to say, the  
20 service traffic flow information of a service session is obtained and added into the service traffic flow classification table when the session is established; and the service traffic flow information of the session is cancelled from the service traffic flow  
25 classification table at the end of the session.

[0084] The internal functions of the edge router according to the present invention are illustrated in Fig. 6, in which:

[0085] (1) When a service session is initialized, the edge router will receive from the service control equipment or the bearer control  
30 equipment the traffic identity (quintuple or triplet), priority, QoS

class, path (MPLS multi-layer label stack) and bandwidth requirement of the session at the QoS control interface. The edge router then creates an entry in the flow classification table for the flow to record the information.

5 [0086] (2) When the service traffic flow of the session is changed, at the QoS control interface, the service control equipment or the bearer control equipment will notify the edge router to cancel the service traffic flow information prior to the change and set the service traffic flow information following the change.

10 [0087] (3) When the session is completed, the service control equipment or the bearer control equipment will notify the edge router to cancel the service traffic flow information of the session.

[0088] (4) When dealing with packets at the downlink input interface, the edge router queries the service traffic flow classification table,  
15 recognizes the traffic according to the identity thereof, performs the classifying and marking according to the priority and the requirement on QoS class of the flow, performs the shaping and monitoring according to the requirement on bandwidth of the flow, chooses to forward in the best-effort delivery mode of IP or label  
20 with MPLS multi-layer label stack according to the path information of the flow, and sends the packets into the LSP pipe or the virtual MPLS network of this class of traffic at the uplink output interface. The uplink output interface perform classification and conditioning (including measuring, marking, dropping, shaping and monitoring of  
25 the MPLS packets) of the LSP traffic according to the LSP attribute(s), when it sends the packets.

[0089] (5) The network core node pops out and forwards the labels according to the MPLS multi-layer label stack and priority of MPLS packets that the edge router marked in the packet header, and measures,  
30 drops, shapes and monitors the LSP traffic according to the LSP

attribute(s).

[0090] Fig. 7 shows the block diagram illustrating the structure of the system according to an embodiment of the present invention, in which:

5 [0091] The present invention provides an apparatus for providing QoS guarantee, which includes: a service traffic flow information obtaining means, for creating a service traffic flow classification table; a label switching path establishing means, for establishing a plurality of label switching paths; a label switching path  
10 configuring means, for configuring the attributes of the label switching paths; and a first performing means, for performing the classification and conditioning of the service traffic flows entering into the core network according to the service traffic flow classification table; a second performing means, for forwarding the  
15 processed service traffic flow according to the attributes of the label switching paths.

[0092] The means described above may refer to the downlink interface 701, the uplink interface 702, the QoS control interface 704 and the path management means 707 in Fig.7. Particularly, said service  
20 traffic flow information obtaining means corresponds to the service information obtaining means 707 in Fig. 7, said label switching path establishing means corresponds to the label switching path establishing means 708 in Fig.7, said label switching path configuring means corresponds to the label switching path  
25 configuring means 709 in Fig.7, said first performing means corresponds to the downlink interface 701 in Fig.7, and said second performing means corresponds to the uplink interface 702 in Fig.7.

[0093] In addition, in Fig.7, the QoS control interface 704 further includes a service traffic flow information storage means 706, which  
30 is used to store the service traffic flow classification table created by the service traffic flow information obtaining means 705.

[0094] As shown in Fig.7, in addition to the specific sub-means mentioned above, the edge router 70 based on the means for providing

QoS guarantee according to the present invention also includes a configuration management interface 703.

[0095] The system for providing QoS guarantee based on the above edge router as described in Fig.7 includes: service control equipment 71,  
5 resource control equipment 72, and edge router 70.

[0096] In which the edge router 70 includes:

[0097] a downlink interface 701 for receiving the IP service traffic flows; a uplink interface 702 for forwarding the IP service traffic flows received by the downlink interface; a configuration management  
10 interface 703 coupled to the downlink interface and the uplink interface respectively, for configuring the parameters of the edge router; a QoS control interface 704 coupled to the downlink interface, for obtaining and storing the service traffic flow classification information, the QoS control interface 704 includes:  
15 a service traffic flow information obtaining means 705 for obtaining the service traffic flow information and a service traffic flow information storage means 706 for storing the obtained service traffic flow information; a path management means 707 for managing the transmission path of the service traffic flow, the path  
20 management means 707 including: a label switching path establishing means 708 for establishing the label switching path for transmitting the service traffic flow, and a label switching path configuration means 709 for configuring the attribute(s) of the label switching path.

25 [0098] Firstly, a number of LSPs are configured statically by the label switching path configuration means in the path management means, or established dynamically by the label switching path establishing means via CR-LDP or RSVP-TE signaling, thus constructing an edge-to-edge LSP concatenated pipe or MPLS virtual network on the  
30 core network.

[0099] Thus, when a service session is initialized, the service traffic flow information obtaining means obtains the traffic identity (quintuple or triplet), priority, QoS class, path (MPLS multi-layer label stack) and bandwidth requirement of the session

at the QoS control interface from the service control equipment or through the resource control equipment, and then stores the information into the service traffic flow information storage means.

[00100] The edge router receives and handles packets at the downlink  
5 interface, lookups for the service traffic flow information stored in the service traffic flow information storage means, recognizes the service traffic flow according to the traffic identity, performs classifying and marking according to the priority and the QoS class requirement of the flow, performs shaping and monitoring according  
10 to the bandwidth requirement of the flow, and selects to forward the packets in the best-effort delivery mode of IP or to stamp the packets with MPLS multi-layer label stack, and sends the packets to the LSP pipe or the virtual MPLS network of this class of traffic at the uplink output interface. The uplink output interface perform classification  
15 and conditioning (including measuring, marking, dropping, shaping and monitoring of the MPLS packets) of the LSP traffic according to the LSP attribute(s), when it sends the packets.

[00101] When the service traffic flow of the session is changed, at the QoS control interface, the service control equipment or the  
20 resource control equipment will notify the edge router to cancel the service traffic flow information prior to the change and set the service traffic flow information following the change.

[00102] The network core node pops out and forwards the labels according to the MPLS multi-layer label stack and priority of MPLS  
25 packets marked in the packets header by the edge router, and measures, drops, shapes and monitors the LSP traffic according to the LSP attribute(s).

[00103] Therefore, the system provides an exact QoS guarantee and a QoS routing control for the applications between the edges of the  
30 core network through the embodiments of the present invention, so as to meet the requirement for a packet-based network to support various services.

[00104] Although the present invention has been described with reference to certain embodiments, it is obvious to the skilled in

the art that many variations and changes in the present invention  
may be made without departing from the spirit of the present invention,  
and it is intended that the appended claims cover theses variations  
and changes without departing from the spirit of the present  
5 invention.
